Abstract. Sound methods of analysis and comparison of software processes are crucial for such tasks as process understanding, process correctness verification, evolution management, process classification, process improvement, and choosing the appropriate process for a certain project. The purpose of our research is to lay the foundations for a systematic and rigorous comparison of processes by establishing fixed methods and conceptual frameworks that are able to assure that comparison efforts will yield predictable, reproducible results. The analysis framework presented here assumes that the comparison will be done relative to a fixed standard feature classification schema for the processes used, and with the use of a fixed formalism for modeling the processes. The aspect of the system described in this paper is focused on functional analysis of processes according to the predefined comparison topics, well formedness constraints, and instrumented agents. The paper describes our experience using our analysis system and its application to a logistics software process from the telecommunication domain.

1 Introduction

This work presents a novel approach for analyzing and comparing software processes that enables one to significantly increase the objectivity and repeatability of comparisons. To our knowledge, this is the first attempt at a partially automated analysis and comparison of software processes based on the artifacts they produce. While our work focuses on the application of our analysis system to software process analyses and comparisons, it is more general. It is also applicable in domains other than software process, such as data-based comparison of software applications for evaluation of continuous program optimization techniques ([10]).

It is our belief that certain tasks (e.g. software development) are very unlikely to be completely automated in the foreseeable future if ever. Thus there will be a need for software process systems with human involvement in their execution. We believe that the operation of such systems can be properly described and analyzed with the use of the concept of a software process as introduced in [12].

One of the hallmarks of a mature scientific or engineering discipline is its ability to support the analysis, comparison and evaluation of the artifacts with
which it deals. Systematic analyses and comparisons rest upon classification. Thus we believe that the establishment of a discipline of process engineering requires the development of techniques and structures for supporting the classification, comparison, verification, evaluation, and improvement of processes. Systematic, rigorous and automatable analysis techniques can help achieve the goals of process engineering.

The analysis system discussed here assumes that the analyzed and compared processes are in the same problem domain and have a similar purpose, but might have certain differences in how they achieve their goals starting from the input of the same kind and providing output of the same kind. Our approach is based on the analysis and comparison of artifacts produced by the processes along the execution paths prompted by similar input (e.g., similar formal requirements for a software system fed to different software development processes). Thus our approach also makes an assumption that the intent of the analyzed processes is in response to the similar input is comparable and produces comparable artifacts.

In this paper we describe our experience analyzing and comparing two versions of a telecommunications logistics process, what results we get from the process analysis, how our system compares to other approaches, and lessons learned from the experience.

2 Logistics process example

As our example we used a telecommunications ordering process employed by Telcordia. The ordering process elaborates the activity of adding a service to a customer. This company uses a proprietary process specification language for rigorous specification of such logistics processes. Their logistics processes also use a predefined set of artifact formats. In addition to the format specification, there is a set of well-formedness conditions defined for the artifacts. One of the challenges the developers of these processes face is the task of change management. After a change is made to the process the developers have to make sure that the process still produces artifacts complying with the well-formedness conditions. If the new version of the process produces an undesirable result then the developers have to find out the cause. This is not always as trivial as it would seem even for relatively small processes as not a single developer understands the process in its entirety. There are also different possible interpretations of the process by developers. The suggested comparison approach alleviates some of these problems by providing a rigorous analysis of process artifacts and suggesting possible causes for the differences based on such an analysis.

The study assumed that two seemingly identical versions of the same process need to be compared to find out if the artifacts produced comply to a certain well-formedness condition, and to point out the reason for the differences if there are any. Such a set-up is likely to highlight the benefits of the artifact-based trace analysis technique that can be used to complement the static analysis of the process template specification such as by Jamieson Cobleigh et al. ([5]).
The representation of the motivating example process template is depicted in Fig. 1. We use the Little-JIL process language ([3]) to show software processes in this paper. The visual representation of the Little-JIL is based on a functional decomposition. The steps are depicted as rectangles with a step’s name above the rectangle. The steps’ interfaces include specification of an agent class (agent: prefix)\(^1\), local parameters (loc: prefix), input parameters (in: prefix, and output parameters (out: prefix). The data flow is depicted along the decomposition links: the inscriptions near the arrow into a step contain input parameters and that near the arrow out of a step contain output parameters. A complete process specification also includes the resource model that specifies the agents available in the environment, the artifacts specification, and the agents’ problem solver components specification that define the transformations from input artifact formats to output ones. The process program declares the agent classes for steps. The actual agents are bound to steps during process execution, therefore it is possible to run the same process template in different environments.

An example of a well-formedness condition for this telecommunications ordering process is the need to base voice communication service on a data communication service. If the ordering process does not establish that a customer ordering the voice communication also needs the data communication then the process creates malformed artifacts that result in billing the customer for the voice service that will not function. To avoid this scenario the executing software process (including the template and functionality of the agents responsible for performance of the steps) has to be shown to comply with the well-formedness condition. Any differences and their possible causes must be found, be they in the

\(^1\) An agent is an entity responsible for execution of a step.
process template or agent functionality, and must be reported. Our comparison approach suggests a rigorous and automated way to provide these results.

3 Steps in analyzing and comparing processes

In this section we discuss the use of an analysis system to analyze and compare the example processes. Figures 2 and 3 illustrate the steps required by the analysis system illustrated in the Little-JIL.

The current implementation of the process focuses on an artifact-based analysis and comparison of two software processes. The software processes are assumed to have structured artifacts with predefined formats such that the processes specify transformations between the artifact formats.

The process of analysis and comparison shown in Fig. 2 is automated by a toolset. The steps for process execution and trace analysis are completely automated. The rest of the steps such as creation of the base framework, process modeling, comparison topics specification have to be executed by a user in a systematic way by following guidelines. The toolset assists the user in executing the non-automated steps. For instance, it provides the Artifact Meta-Format for artifact base framework specification and an agent framework for process specification. The non-automated steps are provided with guidelines for a systematic manual execution.

3.1 Artifact ontology specification

The analysis process starts with constructing an initial base framework (BF) for the artifact section (step Construct initial BF). The base framework
denotes a problem domain specific framework for artifacts, software process decomposition units, and process features that can be derived on their basis. The base framework can be thought of as a classification schema or ontology that provides guidelines for grouping comparable activities, artifacts, or features of software processes from the same problem domain. Software processes are likely to be in the same problem domain if their purpose and functionality overlap.

The step is decomposed into the Tag same meaning elements and Classify artifact elements substeps to be executed sequentially. This step has a substantial subjective involvement of a human user. The BF can be constructed either from an existing ontology or it is generalized from the artifact formats of the analyzed processes. The goal is to identify the semantically overlapping portions of the artifact formats and tag the semantically similar elements of those formats. This is done in the Tag same meaning elements substep based on the source descriptions of the processes Proc A and Proc B. The output of this substep is a table of correspondence of artifact elements from the original process descriptions and their common naming. The correspondence is needed only between artifact elements in the overlapping portion of the semantics of artifacts. Such an overlapping is likely to exist in processes from the same problem domain and with the same purpose.

In the case of our analysis system we used a common artifact meta-format (AMF) and the artifact element naming conventions for tagging. Thus artifact elements are classified according to the AMF (step Classify artifact elements) and artifact elements with the same meaning are named the same in the process models and artifacts of the same class. The Tag same meaning elements substep precedes the Classify artifact elements since it is beneficial to reduce the number of elements to be classified. This reduction is the result of giving the same names to the elements with the same meaning, so the classification decision is made only once for both same named elements from different processes. In our example the BF corresponds to the formats of artifacts used by the telecommunications process. The process’s authors at Telcordia have already specified the artifact formats rigorously. Since the two analyzed processes use the same ar-

  </MetaLinkClass>
</Node>

Fig. 4. Example of BF specification

tifact formats the task of identifying common ontology (BF) is simplified. The categories of the artifact elements map directly to the categories of the ontology. To obtain the BF specification in our example we wrote every artifact template from Telcordia’s source process specification in the AMF. Thus we obtained BF specification for all categories in artifacts used by both analyzed versions of the process: customerData, order, billDBupdate, FQDN, FQDNSpec, features, modemConfig, IPaddress, preorderOutcome, configOutcome. An example of BF specification is shown in Fig. 4. This figure shows specification of BF artifact categories customerData and association. The category specifications also indicate their properties. The actual artifacts used by pre-ordering processes would contain elements that map to these categories and that might be considered their instances. A user would specify the BF categories manually using the Artifact Meta Format to describe the artifact BF categories found in the original description of the analyzed or compared process.
3.2 Process modeling

Once the artifact section of the BF is defined, the modeling of the processes in the same executable process modeling formalism can proceed. The input to this step includes the base framework (BF), process modeling formalism (MF), artifact meta-format (AMF), and the source description of the analyzed processes Proc A and Proc B. It is preferable to feed rigorous specifications of processes elaborated to the level of manipulation of the lowest level decomposition units of artifacts.

This step is further decomposed into modeling of the individual processes that can proceed in parallel. This step may require substantial human involvement but can be automated in the case if the source descriptions are rigorously defined by building a translator from the formalism used in the source descriptions to the common formalism used for analysis.

The expressiveness of the process formalisms can influence the analysis results if they do not allow modeling of the artifact elements or steps that manipulate them related to the comparison topics. The output of the modeling step consists of the process models in the common modeling formalism (ModelA, ModelB). In our implementation we use the Little-JIL as the common modeling formalism for process analysis and comparison. Thus the modeling involves representation of the functional decomposition of the process, specification of the process step interfaces, specification of the artifact formats in the AMF, specification and development of the agents to execute the steps, instrumentation of the agents per a step kind, specification and development of the step-specific GUIs, and the definition of the environment to be the same for both processes (the developed agents are included into the environment).

The original Little-JIL has been extended to generalize the agent and instrumentation specification for individual problem domains. The user must take care not to overspecify the agents beyond the elaboration of the lowest level activities from the source processes. If the source processes assume certain common low level activities then it is advisable to use the same implementation for the agents from both processes. The extended Little-JIL agent architecture allows for reuse of agents’ problem solving components. The Little-JIL artifact specification and the agents must use the artifact formats specified in AMF and complying with the naming conventions for the artifact elements with overlapping semantics.

In our implementation of the analysis system the user would specify the process template in the Little-JIL using the visual editor. An example of a process template we created is shown in Fig. 1. We created two process templates for the analyzed processes.

The user would also specify the agents for the process template using Java and the domain specific agent framework. The framework allows specification of low level agent actions (operations) and then specifying the sets of actions that agents must execute in response to incoming events. In our case the vast majority of events processed by agents are generated by the Little-JIL interpreter. These events carry information about assignment of certain tasks to agents. A task corresponds to an instantiation of process steps. Any task assigned to an
public synchronized void
started(AgendaItemEvent evt) {
    AgendaItem item = evt.getAgendaItem();
    ...
    if (itemName.equals(ResetModemStepName)) {
        ...
        GetFQDN getFQDN = new GetFQDN();
        ArchGraph[] args = {modemConfig};
        ArchGraph_fqm = getFQDN.execute(args, agentStepID);
        item.complete();
        ...
    }
}

Fig. 5. Example of specification of NetworkSvcBots agent’s problem solver

agent goes onto that agent’s agenda list. The agent framework simplifies the
specification of agents by providing a uniform way to specify actions and by pro-
viding a generalized way to instrument the process. Every time a certain agent
executes an action the information about the action’s result is written to the arti-
fact trace. The user only has to specify an action without explicit specification of
the instrumentation code.

The analysis system is limited by the level of elaboration of the source pro-
cesses. If the source process does not describe the activities at the level of ma-
nipulation of artifact elements then this method is unlikely to be applicable. The
generalized instrumentation components simplify the user’s task in the process
modeling stage. Nevertheless, the user must make subjective decisions regarding
continuity of the artifact concerns. The user must decide on the kind of
operation a given agent performs on a given artifact element when performing a
certain step (Operations = (Create, Derive, Retain, Modify)). Thus
every agent, when executing, would add an entry to the annotation lists of the
output artifact elements explaining the operation it performed on that element
and noting agent and step IDs and the timestamp. Also, the user must decide
which output artifact elements are going to inherit the annotation lists from the
input artifact elements. It is this decision that ensures the continuity of arti-
fact concern traces. It is likely that specifics of a given problem domain might
simplify this task. For instance, in logistics processes there is often a limited, pre-
defined set of artifact formats with predefined and explicit relationships between
elements from artifacts of different stages of a process.

Actions comprise the problem solving component of an agent. Part of the
problem solver for the NetworkSvcBots agent is shown in Fig. 5 as an example.
In this figure the started method is invoked in response to an event signifying the
start of a certain task assigned to an agent. If the task’s name is ResetModem-
StepName then the agent will perform the GetFQDN action among others. The
example shows the generalization of action specification. An action is instanti-
ated and then the action is executed when it is passed the input artifacts in a
graph-based Artifact Meta-Format (implemented as ArchGraph). Having a set
of domain specific actions it is fairly easy to create agents using this framework.
The user would create or reuse a set of actions specific to the problem domain of analyzed processes so that to specify agents. Thus agents for the two versions of the pre-ordering process reused a number of actions.

First we wrote a set of actions in Java for the agents of the analyzed processes. The actions used the artifact categories specified in the AMF to represent manipulation of artifacts. For instance, the getFQDN action manipulates the artifact BF category FQDN. Then we wrote the automated agents that used the actions. Our analysis system also allows for specification of human-assisting and human-modeling agents by providing a framework for step-specific GUI specification. For instance, the agents we specified for the analyzed process in Fig. 1 are ServiceRepBots, OrderMgtBots, BillingSysBots, NetworkSvcBots, CallAgentBots.

3.3 Process execution

The next step of the analysis system, Process execution, requires execution of the so modeled and instrumented processes (ModelA, ModelB) on the same input (modelInput). The result of such an execution is a set of two traces of artifacts whose elements are annotated with a list of operations, agents, and steps that were performed on them. The annotation lists in an artifact would cover the trace until this artifact is produced. Thus product artifacts would contain the most comprehensive annotation lists. The annotations of artifact elements are partially ordered by timestamps by construction via the instrumentation code that is run during the process execution. Thus every artifact element relevant to the comparison topic\(^2\) must have a history of all manipulations done to it in the annotation list. This step outputs the traces of artifacts with annotation lists (TraceA, TraceB). The traces follow the execution paths through the process models ModelA, ModelB that correspond to the same input modelInput and hence are considered comparable.

The user obtains the artifact traces automatically by starting the Little-JIL environment and running a process specification with the environment containing the domain specific agents. Since the artifact ontology and consequently the artifact formats used by the agents of the processes are the same then it is possible to conduct a meaningful analysis and comparison of the artifacts. In our example we ran the analyzed processes and obtained two traces of annotated artifacts specified in the AMF. Unlike the BF specification in Fig. 4 the artifacts contain the actual elements corresponding to the BF categories. An example of customerData artifact specification is shown in Fig. 6. It was produced automatically by running the process.

3.4 Comparison topic specification

The step for definition and formalization of comparison topics (Formalize Comparison Topics step) can be executed after the initial BF is constructed and in

\(^2\) the one that needs to be checked in order to determine if an artifact complies with a certain comparison topic
parallel with the Process modeling and Process execution. This is reflected by auxiliary decomposition steps Trace and Topics and Obtain traces. This step implies specification of comparison topics in terms of first order logic formulas operating on the artifact elements with common naming conventions. This step outputs Formalized Comparison Topics as a set of first order logic formulas. In the case of our example the comparison topic is whether both processes fulfill the requirement that a voice service must rely on an existing data service in the customer's service configuration. This requirement is reflected in a relationship from the voice service to the data service in the billDPupdate artifact. One version of the process checks for the data service and establishes the necessary relation. The other version omits this action and produces a malformed artifact which would lead to a failure of the service request set-up in a deployed telecommunications process. This comparison topic is formalized as a first order logic rule in the Xlinkit rule specification language ([4]). The formalized comparison topic is phrased as $\forall vs \in voiceservices \exists link \in associations$ s.t. $link.source = vs \land link.destination = ds, ds \in dataservices$. The Xlinkit rule specification we wrote for the comparison topic in our example is shown in Fig. 7.
3.5 Artifact trace analysis

Next, the analysis process calls for analysis of artifact traces TraceA, TraceB by way of consistency checking to the formalized comparison topics. This analysis is done in the Analyze traces step. The step's input consists of Formalized Comparison Topics and annotated artifact traces TraceA, TraceB.

The step's output forms the results of the artifact-based comparison - consistency links between formalized comparison topics and process artifact elements and sets of step/agent combinations ranked by the contribution measure per a comparison topic. One of the main outcomes of such an analysis is comparison of consistency links from the same comparison topic to artifact elements in different processes. The consistency links help highlight whether:

- both comparison processes comply with a certain comparison topic,
- both comparison processes violate a certain comparison topic,
- one process complies with a certain comparison topic while the other violates it.

The annotation lists help point out the steps and agents that are responsible for the analysis outcome. In addition, it is very likely that the sets of step/agent combinations from different traces (processes) corresponding to the same comparison topic are comparable. Such pairs of sets can give insights about the functional similarities or differences between processes and aid the user in making a more objective process comparison.

Choice of initial artifact sets The set of product artifacts quite often is most useful to be used as the initial artifact set because they contain the most comprehensive annotation lists and they are likely to contain all the artifact
elements that need to be checked for comparison topics. Another advantage to this choice of the initial set is high likelihood that the product artifacts are explicitly defined in the process source description. To reduce the amount of computation it is advisable to choose artifacts that are known to be relevant for the chosen comparison topics. Thus, the initial artifact sets ArtSetA1 and ArtSetB1 are defined by the steps Define artifact set A and Define artifact set B. At this point the user can use the developed toolset to specify the artifact sets to be analyzed from the lists of artifacts in the traces. The toolset visualizes the artifacts as graphs based on their Artifact Meta-Format specification. A general layout of the toolset’s interface is shown in Fig. 8. In our example, using the toolset’s interface, we chose the artifact trace produced by one analyzed processes as ArtSetA1 and the artifact trace produced by the other analyzed process as ArtSetB1.

Choice of comparison topics Once the artifact sets are chosen, the user should choose the comparison topic to be used for consistency checking. This is done in the Choose formalized comparison topic step. The process analysis toolset also lets the user to choose the topics from a list of files with specification such as in Fig. 7.

Checking of artifacts’ consistency to formalized comparison topics Once the initial artifact sets for both processes and the formalized comparison topic are chosen, the comparison process runs a consistency checker that produces consistency links between the formalized comparison topics and artifact elements of the analyzed processes. The current implementation of the comparison process uses the Xlinkit consistency checker by Christian Nentwich.
et al. ([4], [11]). Next, the user analyzes the two sets of artifact elements that have consistency links to the same formalized comparison topics, but belong to different processes. By using the toolset, the user clicks the “Analyze” button and receives results as sets of consistency links between the specified comparison topics and artifact elements. The toolset also shows the steps and agents responsible for the consistencies or inconsistencies based on the information collected in the annotation lists of the traces. An example of analysis results is shown in Fig. 9. In the figure the \textit{billDBupdate} artifact is shown as a graph. The rule \textit{wellformed1} corresponds to the comparison topic specified in Fig. 7. It stipulates that any voice service must be based on a data service. In this case the consistency link from the rule’s representation points to the artifact element responsible for the compliance (\textit{Voice service}). The toolset also points out that the step \textbf{Associate Bundle to Feature} and agent \textbf{BillingSysBots} are responsible for the compliance.

In our example, after we chose the artifact sets and chose the file with the comparison topic, we pressed the “Analyze” button and received results representation that indicated the consistency link between the \textit{wellformed1} topic and \textit{voice service} artifact element of the \textit{billDBupdate} artifact for the first process. The toolset also showed it was due to the way agent \textit{BillingSysBots} performed step \textit{Associate Bundle to Feature}. There was no consistency link from the \textit{wellformed1} topic to elements in the artifacts of the traces of the other process. Thus the two processes were functionally different due to actions the \textit{BillingSysBots} agent performed in step \textit{Associate Bundle to Feature}.

4 Selected comparison with other process analysis approaches

In their earlier work on this topic, Xiping Song and Leon Osterweil proposed techniques and structures for a disciplined and rigorous software process comparison, and demonstrated their use by carrying out classifications and comparisons of processes drawn from the narrow and specialized domain of software design processes [13], [14]. These comparisons were guided by a formal comparison process, Comparison of Design Methods (CDM), and were performed according to a fixed base framework. The base framework can be thought of as a classification schema and provides guidelines for grouping comparable activities, artifacts, and features.

The need to compare modeled processes according to a fixed base framework was also recognized somewhat earlier by Sjaak Brinkkemper et al. ([9]). However, their comparison had no guidelines as explicit and formal as the CDM. The BF suggested in ([9]) has a flat structure as well. The content and construction method are different from the BF in our approach. The BF classes in ([9]) are constructed on the basis of the elements of the process and artifact decomposition units of the compared processes.

Analysis of in-place software processes and measurement of the correspondence of a particular process execution to its model have similar goals with process comparison in that they attempt to evaluate processes. Some fairly recent work in these directions has been done by Jonathan Cook and Alexander Wolf ([6], [7], [8]).

While the above mentioned work by Alexander Wolf, David Rosenblum, Jonathan Cook is a kind of retrospective analysis just as ours is, the kinds of properties investigated by them focused on real-time performance of process activities.

One of the more recent approaches in process comparison is by Abrahamsson et al. [1]. The authors present comparison of Agile processes. They use an ad-hoc comparison method for comparing processes by high level topics. The focus of their comparison is on organizational and activity sequencing issues rather than on the functional differences. This is primarily due to the fact that Agile software development processes (such as Extreme Programming) omit any description of the guidelines for artifact transformation by their activities. Instead they focus on organizational and activity sequencing issues.

5 Lessons learned and Future directions

The lessons learned from using our process analysis system to compare and analyze the two versions of the telecommunications logistics processes center around the artifact focus, the substantial amount of preparation, and the utility and advantages of the use of the system.

Artifact Focus. The focus on artifacts produced by processes is a very useful one. First, it represents the raison d'être of processes: the production of
processes and services on the basis of various input artifacts. Second, it avoids the tarpit of the widely varying and differing ways that one might accomplish the same tasks. The focus is on the results of the tasks and activities, which parts of the process affect them in which ways, and whether they have certain desired properties or not. And finally, while the ways in which artifacts may be produced vary widely, the artifacts themselves in the same domain are far more likely to be much less variable and far less the subject of disagreement.

Initially, Substantial Preparation. Process analysis and comparisons do not come for free. There is, at least initially, substantial preparation to set the stage for the analysis system. Currently very few processes are sufficiently specified — in fact, this posed a significant problem in our research: there were very few process descriptions in use that we could find that were defined in enough detail to perform our experiments with our analysis system. However, if we are to mature as an engineering discipline and move out the current craft stage, this will have to change.

While there is substantial initial preparation, it should be noted that this preparation serves in a variety of ways for subsequent analyses and comparisons or processes in the same domain. For example, once the processes have been formally specified, they may be used in a variety of comparisons and analyses. Once the base framework has been established for a given domain, it can basically serve for the analyses and comparisons of other related processes. The same is true for the ontology and well-formedness conditions. They are substantially applicable to other work in the same process domain.

Advantages. First, the most obvious advantage is the level of automation provided by the process analysis system. Once the initial preparation has been done, the rest of the analysis is done automatically depending on what input is provided to the system. This is a significant improvement in the state of the art for process comparisons and analyses.

Second, the various analyses and comparisons are repeatable. The points of variability are well defined and have been determined in the preparation. The only remaining point of variability is that where human responses are required in the execution of the processes and that input is controllable as part of the system execution.

And finally, as understanding of the processes grows, the various automated analyses and comparisons can be extended and evolved in various ways to provide deeper knowledge of the processes under consideration.

Limits. Because of the artifact focus, little has been done at this point to support various useful kinds of process performance analysis. For example, we currently do not support time and cost analyses for process - i.e. comparisons of race and lapse times of processes, nor the amount of effort involved in process execution.
